White matter microstructure and its relation to clinical features of obsessive-compulsive disorder: findings from the ENIGMA OCD Working Group

Piras, Fabrizio ; Piras, Federica ; et al ; Brem, Silvia ; Stämpfli, Philipp ; Walitza, Susanne

Abstract: Microstructural alterations in cortico-subcortical connections are thought to be present in obsessive-compulsive disorder (OCD). However, prior studies have yielded inconsistent findings, perhaps because small sample sizes provided insufficient power to detect subtle abnormalities. Here we investigated microstructural white matter alterations and their relation to clinical features in the largest dataset of adult and pediatric OCD to date. We analyzed diffusion tensor imaging metrics from 700 adult patients and 645 adult controls, as well as 174 pediatric patients and 144 pediatric controls across 19 sites participating in the ENIGMA OCD Working Group, in a cross-sectional case-control magnetic resonance study. We extracted measures of fractional anisotropy (FA) as main outcome, and mean diffusivity, radial diffusivity, and axial diffusivity as secondary outcomes for 25 white matter regions. We meta-analyzed patient-control group differences (Cohen's d) across sites, after adjusting for age and sex, and investigated associations with clinical characteristics. Adult OCD patients showed significant FA reduction in the sagittal stratum ($d = -0.21$, $z = -3.21$, $p = 0.001$) and posterior thalamic radiation ($d = -0.26$, $z = -4.57$, $p < 0.0001$). In the sagittal stratum, lower FA was associated with a younger age of onset ($z = 2.71$, $p = 0.006$), longer duration of illness ($z = -2.086$, $p = 0.036$), and a higher percentage of medicated patients in the cohorts studied ($z = -1.98$, $p = 0.047$). No significant association with symptom severity was found. Pediatric OCD patients did not show any detectable microstructural abnormalities compared to controls. Our findings of microstructural alterations in projection and association fibers to posterior brain regions in OCD are consistent with models emphasizing deficits in connectivity as an important feature of this disorder.

White matter microstructure and its relation to clinical features of obsessive–compulsive disorder: findings from the ENIGMA OCD Working Group

Abstract

Microstructural alterations in cortico-subcortical connections are thought to be present in obsessive–compulsive disorder (OCD). However, prior studies have yielded inconsistent findings, perhaps because small sample sizes provided insufficient power to detect subtle abnormalities. Here we investigated microstructural white matter alterations and their relation to clinical features in the largest dataset of adult and pediatric OCD to date. We analyzed diffusion tensor imaging metrics from 700 adult patients and 645 adult controls, as well as 174 pediatric patients and 144 pediatric controls across 19 sites participating in the ENIGMA OCD Working Group, in a cross-sectional case-control magnetic resonance study. We extracted measures of fractional anisotropy (FA) as main outcome, and mean diffusivity, radial diffusivity, and axial diffusivity as secondary outcomes for 25 white matter regions. We meta-analyzed patient-control group differences (Cohen's d) across sites, after adjusting for age and sex, and investigated associations with clinical characteristics. Adult OCD patients showed significant FA reduction in the sagittal stratum ($d = -0.21$, $z = -3.21$, $p = 0.001$) and posterior thalamic radiation ($d = -0.26$, $z = -4.57$, $p < 0.0001$). No significant association with symptom severity was found. Pediatric OCD patients did not show any detectable microstructural abnormalities compared to controls. Our findings of microstructural alterations in projection and association fibers to posterior brain regions in OCD are consistent with models emphasizing deficits in connectivity as an important feature of this disorder.

Introduction

Abnormalities in cerebral white matter (WM) are relevant to models of anomalous brain circuitry that posit deficits in connectivity in obsessive–compulsive disorder (OCD). OCD has a childhood onset in over 50% of all cases, and most childhood-onset OCD cases persist into adulthood¹. Diffusion tensor imaging (DTI) allows the study of WM at the microstructural level through the analysis of intrinsic, three-dimensional diffusion properties of water within brain tissues². Prior DTI studies in OCD^{3–5} suggest

that microstructural alterations are present in a number of WM areas. However, results across studies are inconsistent, with contrasting or conflicting effects of OCD on DTI metrics⁶. Sources of heterogeneity may include methodological factors (e.g., imaging acquisition and data processing), clinical characteristics, and variations in demographic or socioeconomic factors. More importantly, sample size variations may impact reported findings, as small studies may have insufficient power to detect subtle alterations⁷.

Brain imaging consortia offer new opportunities, pooling data and findings from around the world to achieve an appropriate sample size. The OCD working group of the Enhancing Neuro-Imaging Genetics through Meta-Analysis (ENIGMA) consortium⁸, is one such collaboration.

Previous findings from the working group focused on subcortical and cortical brain gray matter abnormalities, using subcortical volumes, cortical thickness, and surface area quantification algorithms. An initial analysis of data from 3589 individuals showed distinct subcortical volume abnormalities in adults (smaller hippocampal and larger pallidal volumes) and unmedicated children (larger thalamic volume) with OCD⁹. The second study focused on cortical gray matter differences and showed a lower surface area for the transverse temporal cortex and a thinner inferior parietal cortex in adult patients. In pediatric OCD patients compared to healthy controls, significantly thinner inferior and superior parietal cortices were found¹⁰. Medication status was associated with structural differences in both pediatric and adult OCD.

Here we aimed to investigate WM microstructural alterations in adult and pediatric OCD using data from the ENIGMA OCD working group, in the subset of participants that had collected diffusion magnetic resonance imaging (MRI). DTI metrics in 700 adult patients were compared to those of 645 adult controls, and separately, 174 pediatric patients were compared to 144 pediatric controls. Analyses also aimed to investigate associations between WM microstructure and demographic and clinical variables. As prior meta-analytic findings in frontal and callosal regions have been inconsistent (with either higher¹¹ or lower^{3,11} fractional anisotropy (FA) in anterior midline tracts), with more homogenous findings for fronto-temporal and fronto-parietal intra-hemispheric bundles, we expected to find microstructural alterations (as reflected by lower FA^{3,4,6,11}) in the long tracts connecting frontal regions to posterior temporal, parietal and occipital association cortices.

Methods

Study dataset

The ENIGMA OCD Working Group includes 19 international research institutes. Previous literature (including studies from the present Working Group^{9,10}) showed different patterns of effects in pediatric and adult cohorts; thus, we performed separate meta-analyses for adult and pediatric data. Globally, we analyzed data from 1345 adults (including 700 OCD patients and 645 controls, aged ≥ 18) and 318 children (including 174 OCD patients and 144 controls). The diagnosis of psychiatric disorders including OCD and other comorbid conditions (if any) was made using a structured or semi-structured interview; the Structured Clinical Interview for DSM-IV [(First et al.¹²) $n=9$ datasets], the Mini-International Neuropsychiatric Interview [(Sheehan et al.¹³) $n=3$ datasets], or the schedule for affective disorders and schizophrenia for school-aged children: Present and Lifetime Version [K-SADS-PL¹⁴; $n=7$ datasets]. Patients were administered the Yale-Brown Obsessive–Compulsive Scale (YBOCS)¹⁵

and the Child YBOCS¹⁶ to assess symptom severity. These tools are clinician-rated, 10-item scales, with each item rated from 0 (no symptoms) to 4 (extreme symptoms; total range, 0–40), with separate subtotals for the severity of obsessions and compulsions.

Common exclusion criteria across sites included: (1) history of psychoactive substance dependence or abuse during lifetime, (2) history of neurologic illness or brain injury, (3) presence of any brain pathology as instantiated by standard magnetic resonance imaging (MRI) exams (including T1-weighted and standard clinical sequences), (4) dementia diagnosis according to DSM-IV-TR criteria.

Tables 1 and 2 show the demographic and clinical characteristics of the participants from each site.

All local IRBs approved the use of measures extracted from completely anonymized data.

Image acquisition and processing

Harmonized preprocessing, including brain extraction, eddy current correction, movement correction, echo-planar imaging-induced distortion correction and tensor fitting, was carried out at each site, using protocols and quality control pipelines provided by the ENIGMA-DTI working group (<http://enigma.ini.usc.edu/protocols/dti-protocols/>) and already employed to pool harmonized DTI analyses from around the world^{17–19}.

Once tensors were estimated, each site conducted a harmonized image analysis for FA quantification using the ENIGMA-DTI protocol, consisting of the tract-based spatial statistics (TBSS)²⁰ analytic method modified to project individual FA values to the ENIGMA-DTI skeleton. Tract-wise regions of interest (ROIs), derived from the Johns Hopkins University²¹ WM parcellation atlas, were used to extract the mean FA across the full skeleton and mean FA values for 25 ROIs.

Diffusivity measures (i.e., mean diffusivity (MD), axial diffusivity (AD), and radial diffusivity (RD)) were also derived for secondary analysis (i.e., the analyses were performed only in those WM regions, if any, where FA was significant). In the main analyses, we combined left and right ROI across hemispheres, as we had no a priori hypotheses regarding lateralized effects on FA.

Statistical analysis

At each site, Cohen's d effect sizes were calculated for differences in FA between patients and healthy controls. Age, sex, age-by-sex interaction, and quadratic covariates of age² and age²-by-sex interaction were included in the model, as linear and nonlinear age and sex interactions have been reported for FA¹⁷. Subsequently, a random effects meta-analysis was run at the coordinating site using Comprehensive Meta-Analysis (CMA, version 2, Biostat, Englewood, NJ) to combine individual site effect sizes. Heterogeneity scores (I^2 ; lower values indicate lower

variance in the effect size estimates across studies) were also computed for each test.

Effect sizes are reported as overall Cohen's *d* values for case/control effects and *z*-scores, and were considered significant if $p < 0.05$. The stability of the overall effect size estimate was tested using a 'leave one out' sensitivity analysis. This analysis shows how the overall effect size changes if one dataset at a time is removed, assessing whether potential results are site-dependent with between-sites variations potentially deriving from variability in study population characteristics (sampling error). Furthermore, to ascertain whether the estimated effect size varied as a function of clinical characteristics, mixed-effects meta-regressions were performed on FA, using age of onset, duration of illness, symptom severity, and percentage of medicated patients in the patients' dataset as regressors. The influence of medication status was also explored through a mixed-effects sub-group analysis, comparing effect sizes in medicated ($n = 8$) and unmedicated ($n = 3$) patient cohorts. These analyses were primarily run in those WM areas where effect sizes were significant and stable according to the leave-one-out analyses. Ancillary analyses explored the effect of clinical variables on FA also in WM areas where only partly stable results were observed (i.e., where the removal of 1 or 2 studies affected significance)

Results

Demographics and clinical characteristics of the participants in each site are shown in Tables 1 and 2.

Adult Cohort

Table 3 indicates the 5 out of 25 regions with lower FA in patients compared to controls. These are the genu of the corpus callosum (GCC, $d = -0.17$, $z = -2$, $p = 0.045$), the posterior corona radiata (PCR, $d = -0.16$, $z = -2.38$, $p = 0.017$), the posterior thalamic radiation (PTR, $d = -0.261$, $z = -4.57$, $p < 0.0001$), the sagittal stratum (SS, $d = -0.21$, $z = -3.21$, $p = 0.001$) and the uncinate fasciculus (UNC, $d = -0.18$, $z = -2.49$, $p = 0.013$) (see Fig. 1).

Heterogeneity scores revealed a significant high variance for GCC ($I^2 = 53.61$, $p = 0.018$) only, whereas PCR ($I^2 = 26.25$, $p = 0.19$), PTR ($I^2 = 6.61$, $p = 0.38$), SS ($I^2 = 24.43$, $p = 0.21$), and UNC ($I^2 = 37.4$, $p = 0.1$) showed non-significant variance between sites.

The sensitivity analysis showed that PTR and SS were the only WM tracts where the removal of individual datasets did not affect significance. For the other WM tracts results are more controversial, since for GCC the exclusion of six sites determined a loss of significance of the model, while for PCR and UNC the exclusion of two

sites determined a loss of significance of the model (see Supplementary Table 1).

As secondary analyses, we also investigated diffusivity measures (i.e., MD, AD, and RD) in those WM regions where FA was significantly reduced in OCD. Results revealed that patients diagnosed with OCD showed higher MD in the SS ($d = 0.21$, $z = 2.75$, $p = 0.006$) and higher RD in PTR and SS ($d = 0.16$, $p = 0.002$ for PTR and $d = 0.21$, $p = 0.007$ for SS). No significant results were found for AD.

As stated, meta-regressions were primarily run in regions where effect sizes were significant and stable (i.e., PTR and SS). In the SS of adults diagnosed with OCD, lower FA was significantly associated with younger age of onset ($z = 2.71$, $p = 0.006$), longer duration of illness ($z = -2.09$, $p = 0.036$) and a higher percentage of medicated patients ($z = -1.98$, $p = 0.047$; see Fig. 2). Mixed-effects sub-groups analysis showed a significant difference (q value_(df = 1) = 5.27,

$p = 0.022$) between the effect sizes in medicated ($N = 544$, $d = -0.274$, $p < 0.0001$) and unmedicated ($N = 158$, $d = 0.046$, $p = 0.72$) patients. No relationship was found between FA values of the PTR and clinical measures. No relationship was found between FA and YBOCS scores.

Ancillary analyses in those WM areas where results were unstable according to the leave-one-out analyses (i.e., PCR and UNC), revealed that lower FA was associated with longer duration of illness ($z = -2.308$, $p = 0.021$) and higher percentage of medicated patients ($z = -2.817$, $p = 0.005$) in the PCR, and with higher percentage of medicated patients ($z = -2.453$, $p = 0.014$) in the UNC.

Pediatric cohort

In the pediatric cohort, patients showed no detectable FA abnormalities in any of the regions studied (see Table 4 for statistical details).

Discussion

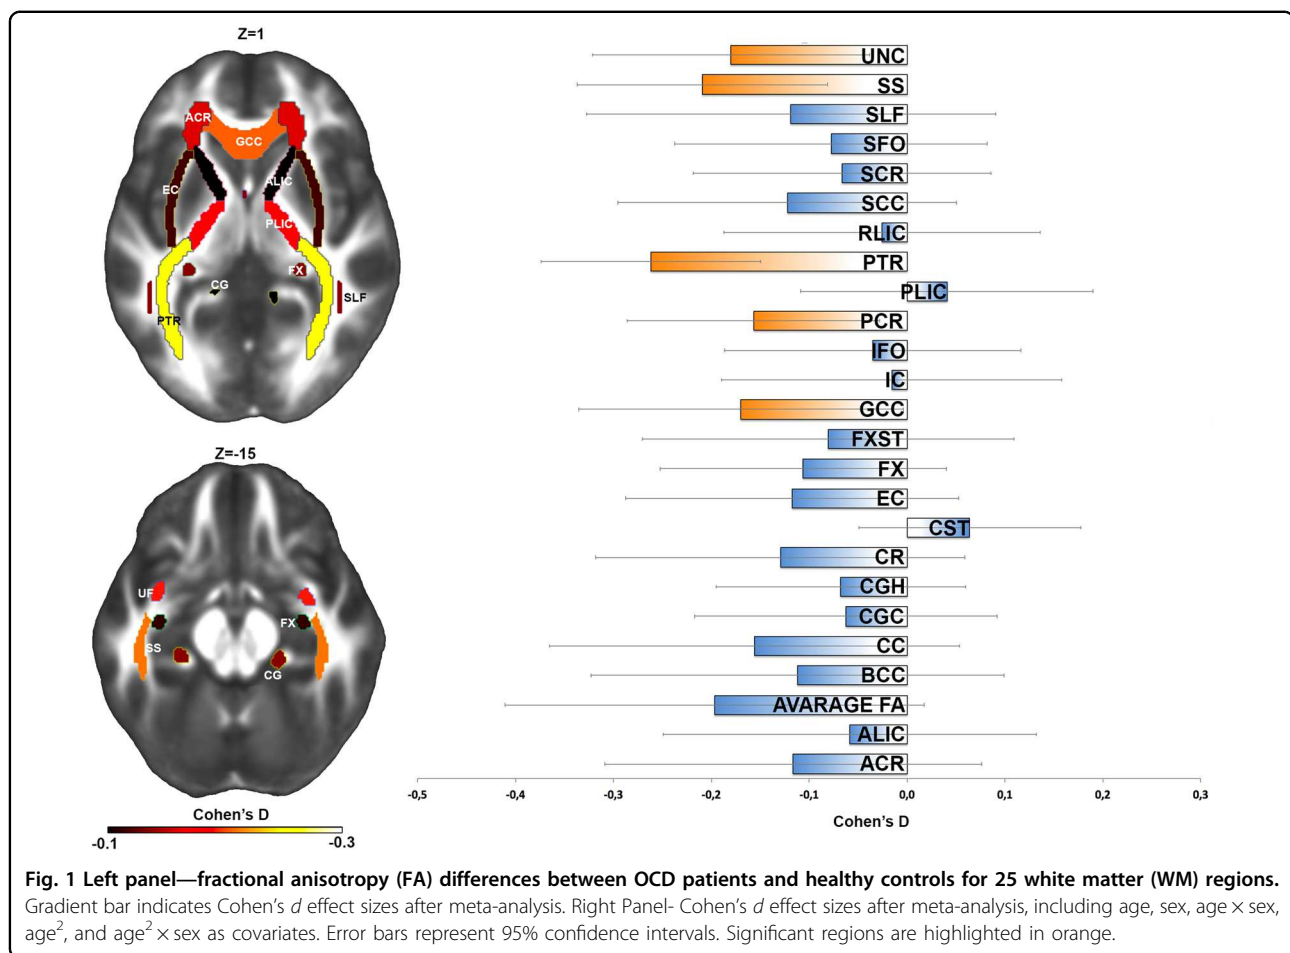

In the largest coordinated meta-analysis of WM in OCD to date, we demonstrated specific regional WM alterations in adults with OCD, with lower FA in GCC, PCR, PTR, SS, and UNC. Such results were stable and independent of sampling error in the PTR and SS only. Secondary analyses on other diffusion parameters revealed that OCD showed higher MD in the SS and higher RD in PTR and SS.

Meta-regressions indicated that lower FA in the SS is associated with younger age at onset, longer duration of illness, and being on medication, but not with symptom severity suggesting that—as observed for cortical thickness and subcortical volumes in OCD—the reported alterations may be markers of the disorder. We did not

find case-control differences in WM microstructure of pediatric subjects.

A role for cerebral WM and oligodendrocytes (the myelinating cells of the central nervous system) in the pathophysiology of many psychiatric disorders has been supported by growing research evidence^{4,22}, suggesting abnormalities of myelination status as a possible pathogenic mechanism²³. Specifically, altered myelin-related maturational growth may explain the enhanced risk for psychiatric disorders during the transition from childhood to adulthood^{24,25}, an age window of intense ongoing brain development²³.

Although FA is a general measure of microstructure—including variation in regional myelination levels, such as axon demyelination or loss, myelin loss or increased

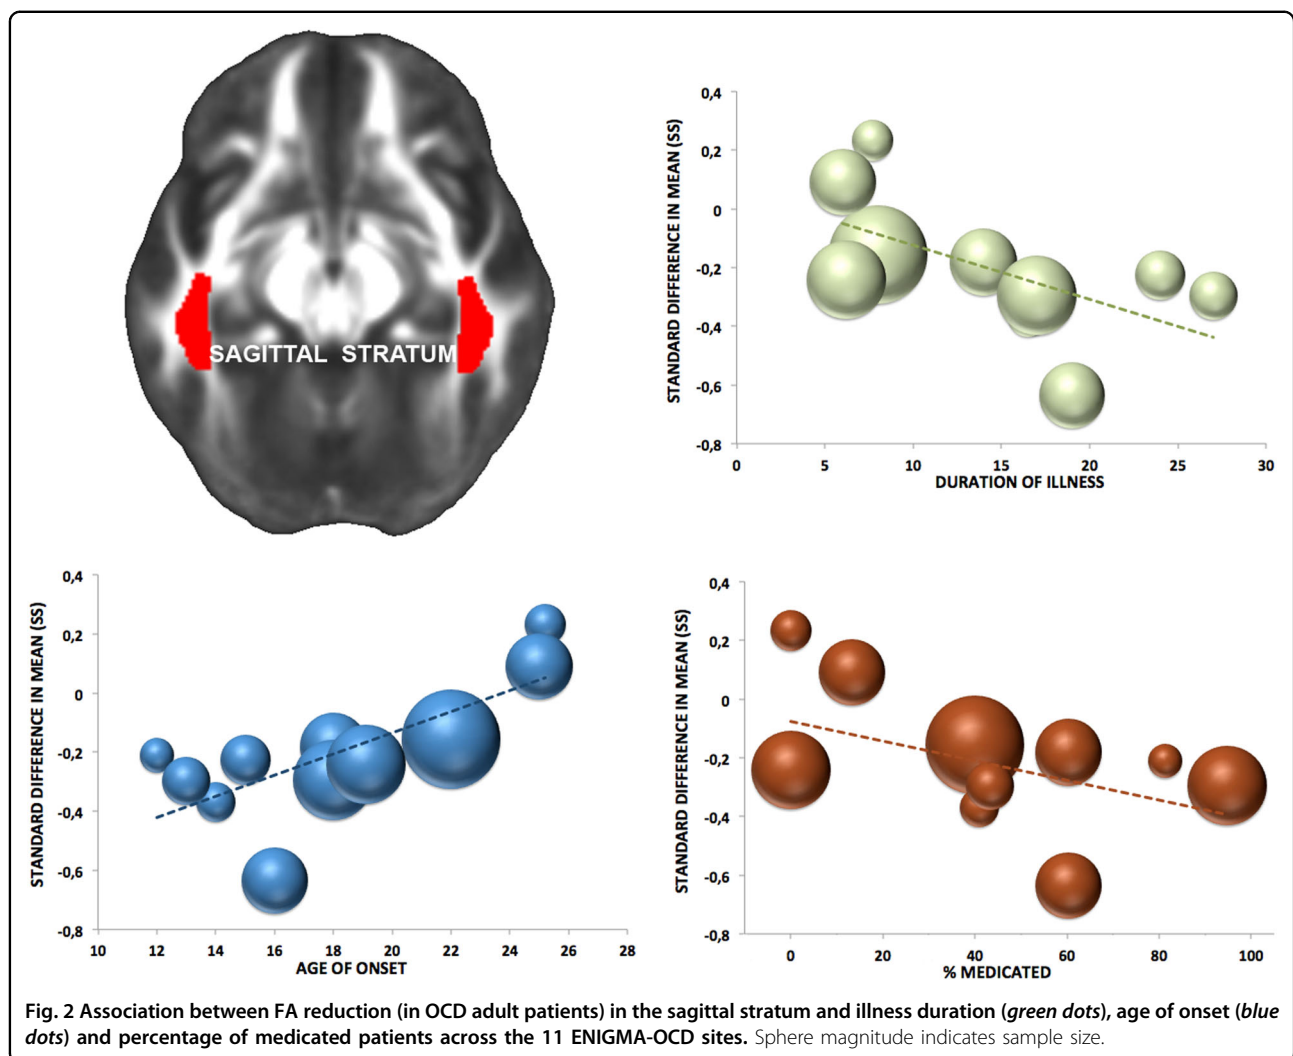

extracellular space—it does not provide a physiologically specific explanation of WM abnormalities²⁶. In our study, higher MD and RD (and the absence of changes in AD) in the same bundles supports the hypothesis that lower FA reflects a disruption of myelin sheaths^{27,28}, given that RD is a putative myelin marker²⁶.

The association between myelin degradation in the SS and longer illness duration together with the absence of a detectable alteration in pediatric patients, suggest that neuroplastic changes may reflect prolonged symptomatology, since compulsively engaging in a particular behavior or cognitive process has been suggested to alter brain structure^{29,30}. Moreover, symptoms indicative of obsessive-compulsive traits are related to individual myelination over time, even in otherwise healthy samples. This suggests that the mechanisms underlying compulsivity have long-lasting effects on brain development, possibly affecting myelination trajectories during adolescence, with enduring effects into adulthood²³. Alternatively, the paucity of extrinsic factors regulating the development of myelinating glia³¹ could have driven the altered myelination and its association with prolonged illness. Indeed, impoverished environment is both the

cause and the consequence of mental illness in general, and of compulsivity in particular³².

Lower FA in the SS was related to medication status (this was true also for PCR and UNC), and present only in the cohort of medicated patient. Moreover, the effect remained significant across combinations of datasets when only medicated patients were considered. Therefore, we cannot rule out the possibility that medication impacts WM microstructure. Indeed, drug-induced reductions in the FA of several WM tracts may be seen in OCD³³ and long-term treatment exposure may negatively influence the proliferation of oligodendrocytes and their myelination of axons^{27,34–36}. Our findings are consistent with a previous large multimodal meta-analysis³ where increased WM volume and decreased FA were especially pronounced in OCD samples with a high proportion of medicated patients. That said, given the cross-sectional nature of the present study, our interpretation here is a tentative one, and requires confirmation with a longitudinal design.

PTR and the SS (but also the PCR) convey projection fibers to the posterior part of the brain. Thus, our results strengthen the hypothesis that OCD involves abnormalities affecting an extensive network of regions^{11,37}. Both bundles

project to posterior parietal, temporal and occipital cortices, and include many major association fibers (including the UNC) where altered microstructure may be related to clinical phenomenology^{38,39}. Our findings are consistent with a range of work indicating altered connectivity outside the fronto-striatal circuit in OCD. For example, results of a multimodal structural imaging study suggested that patients with OCD show significant alterations of the interrelated gray and WM networks over occipital and parietal cortices, frontal interhemispheric connections, and cerebellum⁴⁰. Also, decreased functional connectivity in the occipital cortex, temporal cortex, and cerebellum has been shown in OCD⁴¹. Finally, there is evidence in OCD of associations between structural and functional alterations in a complex network including, beyond orbitofrontal and cingulate areas, temporal and occipital cortices⁴².

We only partially replicate previous large meta-analytic findings demonstrating the validity of both the classic fronto-striatal model of the disorder³ and the more recent multiple

brain system approach^{11,43}. The present findings are based on the TBSS technique, which by reducing WM tracts into a skeleton, confines statistical testing to a selective group of voxels through a constrained local search for maximal FA. Such an algorithm may therefore produce more consistent results, but also more conservative ones, thus explaining the lack of case/control group differences in more anterior WM structures found in previous meta-analysis where whole-brain WM volumetric and FA studies were combined³.

Notably, in our study WM microstructural alterations in OCD were associated with age at scanning. Specifically, WM alterations were observed in the adult cohort only, and were associated with longer illness duration. These findings, which were unrelated to OCD symptom severity, complement previous evidence of differences between adult and pediatric OCD patients in brain morphological^{3,10,44} and clinical⁴⁵ correlates.

There is evidence that the human brain's protracted myelination^{46,47} underpins myelin vulnerability along a

Table 4 FA meta-analysis metrics for the pediatric sample.

continuum from early to late stages of development and disease⁴⁸. Thus, it has been suggested that pediatric OCD could be a neurodevelopmental disorder with potentially differing patterns of myelination occurring throughout life⁴⁹. Indeed, evidence in healthy subjects indicates that the psychiatric trait of compulsivity is linked to reduced myelin growth that emerges only during adolescence (being present only to a minor extent in childhood) as a result of aberrant developmental processes²³. Alternatively, pediatric OCD might be a developmentally moderated expression of etiologic processes that are shared with the adult clinical phenotype.

A number of limitations of the data analyzed here deserve emphasis. First, although TBSS is a widely used method for voxel-based analysis of WM, addressing issues associated with smoothing and misalignment in DTI group analysis³⁷,

the technique has some limitations. Indeed, by reducing WM tracts into a skeleton, delineating the center of the tracts and projecting onto it only the highest FA value along the projection, some information might be lost⁵⁰, and potential artifacts, resulting from misregistration, might be produced⁵¹. Nevertheless, several test–retest and reliability analyses were conducted by the ENIGMA-DTI working group to ensure reproducibility of measures and effects using this TBSS approach⁵². Future investigations combining various imaging modalities in the same meta-analysis and both pre-analyzed and raw data⁵³ will potentially offer insights that are not apparent from the TBSS approach. Moreover, a word of caution is needed regarding the interpretation of the neurobiological basis of DTI measures since although FA reflects the myelination, orientational

coherence, and microtubular axonal structure of fibers, other in vivo markers not explored in the present study have been shown to be a more direct reflection of myelination status^{54,55}. Another potential limitation of the present study may lie in the differences in clinical characteristics between the studied patients, particularly in the average age of onset (which ranged from 4 to 49). Since the latter is often calculated retrospectively, a reliable and unanimous method for establishing this important effect moderator is warranted. Also, we were not able to calculate specific dosages of different medication types and analyze medication effects in terms of drug dosages or total time of treatment and, as such, potential detrimental/normalizing effects of different medications could not be tested. Furthermore, while disorder severity was assessed cross-sectionally at the time of the scan, WM integrity reflects a process that occurred longitudinally over time and this could explain the absence of disorder severity effects. Lastly, it is worth mentioning that while the adult cohort analysis had sufficient power to detect the observed effect size, as the sample size was adequate to detect microstructural differences as small as $d = 0.15$, the null result in the pediatric cohort may be a consequence of the relatively small sample size since the power for potentially detecting even very small differences was low (0.32). Nevertheless, this is the largest pediatric dataset investigated in a DTI study of OCD.

In summary, our results clearly indicate a key role in adult OCD for microstructural alterations in projection and association fibers to posterior brain regions. Our meta-regression results related to duration suggest that microstructural alterations may persist during the course of the illness, although longitudinal data are needed to confirm such trajectories. Future studies to investigate the co-occurrence of abnormal WM microstructure, GM volume and metabolic differences in OCD may shed light on the interactions and trajectories of structural and functional alterations in this condition. In particular, longitudinal designs, and collecting information from patients at their illness onset, combined with multimodal MRI approaches, such as volumetric, DTI, fMRI, and MRS will help provide an understanding of the timing and course of brain changes in OCD, and provide greater insight into the mechanisms involved in various stages of OCD, including the long-term effects of medication.

Conflict of interest

The authors declare no competing interests. The study was partially funded by the Italian Ministry of Health (Ricerca Corrente 19, 20).
